Topdressing Nitrogen in Modern Winter Wheat Varieties in Central Russia

By B.I. Sandukhadze and E.V. Zhuravleva

This research found that split N topdressing is not always more efficient than single topdressing on winter wheat in Russia. Modern wheat varieties generally have both the highest yield potential and response to N fertilizers.

Winter wheat is the most important food crop occupying a considerable portion of sowing area in the Non-Chernozem zone of Russia. The Central part of the Non-Chernozem zone has a total cropped area of about 5 M ha and is characterized by variation in climatic conditions. The frost-free period ranges from 112 to 148 days and climate needs to be considered by agricultural producers when selecting both crop management technologies and variety. Winter wheat has the highest potential biological productivity among other cereal crops cultivated in the region.

Winter wheat breeding programs in Central Russia have generated many successful, high yielding varieties—a key to the region’s annual increases in planted area.

Common abbreviations and notes: N = nitrogen; P = phosphorus; K = potassium; KCl = potassium chloride; HCl = hydrochloric acid; M = million.
ter wheat management was standard for the zone with P and K fertilizers broadcast before cultivation at 60 kg/ha for both P2O5 and K2O. Fungicide and insecticide treatments were applied as required along with appropriate herbicide applications.

Spring application of N was done either as a single topdressing [0, 60 (medium rate), and 120 kg N/ha (high rate)] in early spring just after snowmelt, or as split topdressings providing 30+30 and 60+60 kg N/ha (in spring just after snowmelt and during the stem elongation stage) or 40+40+40 kg N/ha (in spring just after snowmelt, during the stem elongation stage, and before flowering). Nitrogen was applied as ammonium nitrate. In this summary, N responses for two cultivars from the current breeding program and two from an earlier program are compared.

### Results and Discussion

Seasonal weather conditions were unfavorable for 3 years of the study as 1999, 2002, and 2007 had low growing season rainfall. Both temperature and moisture regime interact with variety as well as impact leaching and gaseous losses of N from the soil. These varying conditions can be summarized by a hydrothermal coefficient (HTC = ∑P/(0.1∑t)), which combines precipitation (mm) in the given period (P), with the average daily air temperature (t) above 10°C (Selyaninov, 1937). Coefficient values < 1.0 indicate dry weather and values < 0.5 indicate a period of significant drought. There was no significant correlation between HTC and grain yield for the control treatments in the 14 varieties studied, but use of grain yield data from the topdressed N treatments improved this relationship. The correlation coefficient (r) was equal to 0.45 in modern varieties and 0.95 in varieties from the earliest breeding periods. Therefore, the application of N has allowed the varieties to respond to meet their genotypic yield potential in all conditions. Importantly, the application of N increased drought resistance of varieties as shown by the higher relative yield increase due to N application in dry years.

Of interest are the responses to topdressed N of four modern winter wheat varieties, Pamyati Fedina and Moskovskaya 39 from an earlier breeding program, and Galina and Nemchinovskaya 24 from the current program. Our results show that plant height increased with higher N rates with the single N application for all four varieties (Table 1). Varieties had achieved their maximum height with a single application of 120 kg N/ha. Among four studied varieties, the Moskovskaya 39 variety was the tallest and the Nemchinovskaya 24 the shortest. Where N was split, plants appeared to be not as tall if compared with a single N application; however, this decrease was not significant and had no effect on lodging resistance. It should be noted that all four varieties are short-stem varieties, and are generally considered resistant to lodging with increasing N rates.

Some researchers recommend splitting topdressed applications of N fertilizer to better match supply and demand because N can be lost to the environment if applied early in crop growth when uptake is slow. However, our research has shown that splitting N application is not always an efficient measure to increase the yield of winter wheat (Table 1). As is the case for a single topdressing of N, the influence of weather conditions is also large for split N applications, but the effect is often expressed to a lesser extent. The three-factor analysis of variance showed that when N is split-applied “year” accounted for 46% of the variation, while “variety” and “fertilizer” shared the remainder.

Thus, the weather in each year should be considered when assessing N use efficiency, including the effect of fertilizer timing and splitting. For example, the highest yield of Moskovskaya 39, Pamyati Fedina, and Nemchinovskaya 24,
was in the very wet year of 2005, and this was obtained when N was topdressed as two splits applied as 60+60 kg N/ha. On the other hand, Galina gave the highest yield with a single N application at 120 kg N/ha. The highest yield of Moskovskaya 39 and Pamyati Fedina varieties in conditions of sporadic rainfall in 2006 was from a single application of 120 kg N/ha, while Galina and Nemchinovskaya 24 gave the highest yield from the treatment with two splits of 60+60 and 30+30 kg N/ha, respectively.

Agronomic efficiency of N (AEN, Dobermann, 2007) was calculated from these experiments and it varied from 12.7 to 39.0 kg of grain/kg N over 3 years for the single and split topdressing N rates (Table 1). The AEN for Pamyati Fedina increased from 14.5 to 23.7 kg grain/kg N when N was applied in two splits (30+30 kg N/ha) rather than a single topdressing of 60 kg N/ha. This response was seen in each year during our 3-year study. In general, the highest benefit from topdressed N was found in the newer varieties—Galina and Nemchinovskaya 24.

Our research indicates that wheat varieties from the modern period (Nemchinovskaya 24 and Galina) have the highest yield and are more responsive to N fertilizer than the other varieties studied. Our analysis of yield components revealed that N application increases the number of kernels per wheat spike and this increase can be explained by the reallocation of assimilates to wheat spikes during stem elongation. Under the unstable weather conditions in 2006, the highest yields for Pamyati Fedina were with two splits (30+30 kg N/ha) and three splits (40+40+40 kg N/ha). This response was a consequence of higher kernel weight in the case of two splits, but was due to more fertile tillers under three splits. The highest yield for Moskovskaya 39 was from a single topdressing at 120 kg N/ha, but this variety produced considerably more fertile tillers with 30+30 kg N/ha, while 40+40+40 kg N/ha increased both kernel number and kernel weight. Nemchinovskaya 24, like Moskovskaya 39, produced high yields in three splits. In this case, maximum yield was obtained with 30+30 kg N/ha due to more fertile tillers and higher kernel weights, while a high response to 40+40+40 kg N/ha generated a significant increase in fertile tiller number, and the single N application at 120 kg N/ha increased both kernel weight and number per spike. The maximum yield of Galina was attained with two splits of 60+60 kg N/ha and this increase was a consequence of considerable improvement of all yields components.

Our research results indicate a high efficiency of topdressed N in winter wheat although these data also show that split applications are not always more efficient than a single topdressing. The efficiency of either single or split applications of N fertilizer is strongly dependent on weather conditions. According to data obtained in our experiments, modern Russian wheat varieties such as Nemchinovskaya 24 and Galina have both the highest yield and the largest response to N fertilizer.
